ABSTRACT Whole-mount and sectioned *in situ* hybridization was used to identify genes with restricted expression pattern in the presomitic and somitic mesoderm during *Xenopus* early development. Here we report the dynamic expression pattern of six distinct genes differentially expressed in these regions. These include *Xenopus* homologues of *purine nucleoside phosphorylase*, *acetylcholine receptor*, *aspartate aminotransferase*, *glycine amidinotransferase* and brain and muscle isoform *creatine kinases*. *Purine nucleoside phosphorylase* was initially expressed in the marginal zone at gastrula stage and then localized to the tail bud. Although the other genes showed no significantly localized expression at gastrula or neurula stages, they are progressively restricted in the somitic mesoderm as development proceeds. A common feature for these genes is that their deficiency in humans leads to an impairment of several tissue or cell functions. An analysis of their expression pattern could provide information regarding their implication in early development.

KEY WORDS: *purine nucleoside phosphorylase*, *acetylcholine receptor*, *aspartate aminotransferase*, *glycine amidinotransferase*, *creatine kinase*, *somite*, *mesoderm*, *Xenopus*

Introduction

During the early process of skeletal muscle cell differentiation, the specification and commitment of myogenic cells are initiated by the activation of different members of the bHLH myogenic gene family including Myf5, MyoD, myogenin and Mrf4. These genes exhibit distinct expression pattern and have specific function during the specification and differentiation process of muscle cells (reviewed in Buckingham, 2006). They have the activity to induce myogenic conversion in a variety of cultured cells. During the differentiation process of muscle cells, the expression and activity of other genes are required and mutations of these genes result in dysfunction of muscle cells. Thus, identification and analysis of novel genes expressed in the presomitic and somitic mesoderm can provide insight into the molecular mechanism involved in myogenesis and muscle cell function. We have previously used whole-mount *in situ* hybridization approach to identify genes with restricted expression pattern during early development (Bourdela-

et al., 2004). The present study reports the identification and analysis of the spatial and temporal expression pattern of six genes during early development. Two of these genes (*purine nucleoside phosphorylase* and *aspartate aminotransferase*) are novel genes in *Xenopus*. Although the other genes have been previously characterized in *Xenopus*, there was no detailed analysis of their early expression pattern. The cDNA clones corresponding to these genes were obtained by sequencing a gastrula cDNA library and blast search indicates that full-length cDNA sequences corresponding to these clones could be found in the database. Their expression pattern at different developmental stages was analyzed both by whole-mount and sectioned *in situ* hybridization.

Abbreviations used in this paper: AGAT, L-arginine:glycine amidinotransferase; bHLH, basic helix-loop-helix; PNP, purine nucleoside phosphorylase;

Results and Discussion

Purine nucleoside phosphorylase

Purine nucleoside phosphorylase (PNP) catalyzes the phosphorylation of nucleosides and deoxynucleosides, generating ribose 1-phosphate and the purine base, which is an important step of purine metabolism pathway. The lack of such an activity in humans leads to an impairment of T-cell function (Bzowska *et al.*, 2000). The *Xenopus* homologue of PNP has not been described previously. Sequence alignment (Supplementary Fig. S1) indicates that the *Xenopus* protein exhibits 65% and 68% overall identity to its mouse and human homologue, respectively. The gene shows dynamic expression pattern during early development. It is first strongly expressed in the dorsal marginal zone and relatively weakly in the lateral and ventral marginal zones at the early gastrula stage (Fig. 1A). As gastrulation proceeds, the strong expression also extends to the lateral and ventral domain (Fig. 1B). In sectioned gastrula, the transcripts were localized to the deep layer of the prospective neural plate (Fig. 1C). This expression persists until at the end of gastrulation (not shown). At

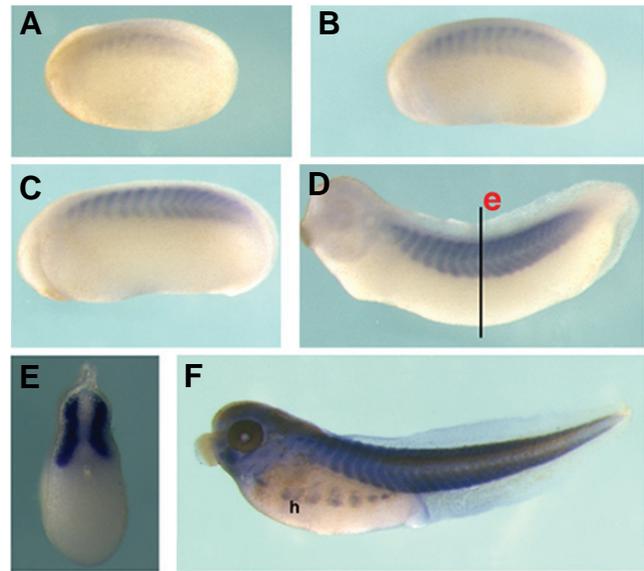

Fig. 1 (Left). Expression of *purine nucleoside phosphorylase*. (A) Vegetal view of an early gastrula (stage 10.5), with a strong expression in the dorsal marginal zone. (B) Vegetal view of a stage 11 gastrula. The transcripts are detected in the entire marginal zone. (C) Section from the line in (B), showing expression in the deep layer of dorsal marginal zone cells. (D) Dorsal view of a stage 15 early neurula. Expression is localized to the posterior region and the entire neural plate. (E) Section from the line in (D), showing expression in the deep layer of neural plate and absence of expression in the somites and notochord. (F) Lateral view of a stage 22 early tail-bud embryo, with the expression essentially detected in the tail bud and the forming otic vesicle (OV). (G) Section from inset in (F), showing expression in deep cells of the tail bud. (H) Lateral view of a stage 28 tail-bud embryo. The expression is restricted in the posterior tip of the tail bud and in the otic vesicle (OV). (I) Section from inset in (H), with higher magnification of the otic vesicle. (J) Section corresponding to inset in (H), showing expression in the tail bud including both unsegmented posterior mesoderm and neural precursor cells.

neurula stage, it is strongly expressed in the posterior region above the blastopore, and in the deep layer of the neural plate, but not in the somites or notochord (Fig. 1D, E). From the end of neurulation or the early tail-bud stage onward, the expression is essentially restricted to the posterior tail-bud region composed of both unsegmented mesoderm and posterior neural tissue, and in the forming otic vesicle (Fig. 1F-J).

Acetylcholine receptor

The nicotinic acetylcholine receptor is a ligand-gated channel that mediates signalling at the vertebrate neuromuscular junction and is consisted of four subunits. In *Xenopus*, there are two α subunits, $\alpha 1a$ and $\alpha 1b$, encoded by distinct genes (Hartman and Claudio, 1990). Although these two α subunits were found to be muscle-specific, there is no detailed description of their temporal and spatial expression during early development (Baldwin *et al.*, 1988; Hartman and Claudio, 1990). The cDNA clone 6D08 that we

identified corresponds to $\alpha 1a$. Sequence alignment indicates that it is highly conserved in vertebrates (Supplementary Fig. S2). It is a maternal mRNA without any detectable localized expression during gastrulation and neurulation (not shown). At the end of neurula stage, it is weakly detected in the formed somites, but not in the posterior presomitic mesoderm (Fig. 2A). This suggests that acetylcholine receptor may function as early as the first somite forms. The somitic expression persists and becomes strong as development proceeds (Fig. 2B-D). In sectioned embryo at the trunk region, it is clear that $\alpha 1a$ subunit is somite-specific and is localized in all the compartments of the somite (Fig. 2E). At larval stage, the expression is also detected in the hypaxial muscle cells and head muscle cells (Fig. 2F).

Aspartate aminotransferase

The cDNA clone 27F11 encodes a protein corresponding to *Xenopus* aspartate aminotransferase. This protein is highly conserved among vertebrates and the *Xenopus* protein shows 81% and 80% overall identity to its mouse and human homologue, respectively (Supplementary Fig. S3). This enzyme is involved in liver glyceroneogenesis (Ferris and Williamson, 1978), but its expression pattern and function during early development in different species remains unknown. At gastrula and neurula stages, there is no localized expression (not shown), but restricted expression in the formed somites becomes evident at the end of neurulation or early tail-bud stage (Fig. 3A). As development proceeds, strong expression can be found in the somites, but not in the posterior presomitic mesoderm. Beginning at stage

30, it can be also detected in the proctodium and pronephric duct, but not yet in the pronephros anlag (Fig. 3B). This expression pattern then persists during late development, with an additional expression site in the pronephros anlag from stage 32 (Fig. 3C, D) onward to at least larval stage (Fig. 3E). At these stages, the transcripts could be also detected diffusely in the ventral region of the branchial arches and in the heart primodium (Fig. 3C, E).

Glycine amidinotransferase

Glycine amidinotransferase or L-arginine:glycine amidinotransferase (AGAT) is one of the proteins strongly conserved (Supplementary Fig. S4) and is involved in the synthesis and uptake of creatine and thus in energy metabolism. This gene exhibits dynamic expression pattern during development. The first detectable expression of *AGAT* is localized in the marginal zone at the early gastrula stage, with a higher level in the dorsal region (Fig. 4A). At the end of gastrulation, it is weakly expressed in the dorsal region corresponding to the presumptive neural plate (Fig. 4B). At the end of neurulation, it is diffusely expressed in the somitic mesoderm and in the ventral endoderm at the trunk region (Fig. 4C). This expression pattern persists during later development and extends to the entire formed somites and the endodermal mass (Fig. 4D, E). In sectioned embryo at the trunk region, it is clear that *AGAT* is localized in the somite and endodermal mass, as well as weakly in the notochord, but not in the neural tube and lateral plate mesoderm (Fig. 4F). At larval stage, strong expression remains in the somites, while the endodermal expression becomes relatively weak. A weak expression can be also found in the hypaxial muscle cells (Fig. 4G). The cDNA clone 4A07 obtained in this study was identical to a previously identified sequence. However, some differences exist between previous

and our present study. Previous analysis by whole-mount *in situ* hybridization detected *Xenopus AGAT* expression in the notochord and gut endoderm, but not in the somites (Zhao *et al.*, 2001). We cannot explain this discrepancy, one possibility might be the probes used in different study. In the present study, we have used the full-length cDNA sequence as a template for probe synthesis (Table 1; Supplementary Fig. S4).

Creatine kinase

As AGAT, creatine kinase (CK) enzymes are remarkably conserved (Supplementary Fig. S5 and S6) and are also involved in energy metabolism. They catalyse the reversible phosphorylation of creatine from ATP. In higher vertebrates, there are two subunits, the brain and muscle isoforms, encoded by two distinct genes (Robert *et al.*, 1990). In *Xenopus*, immunochemical characterization of these two isoforms has been described for larval

and adult tissues (Robert *et al.*, 1990; 1991a, b). However, mRNA expression data of these two genes during early development has been lacking. The cDNA clone 6F01 showed an identical sequence with the *Xenopus* brain isoform *creatine kinase* found in the database (Table 1). The predicted amino acid sequence shows 85% overall identity with the *Xenopus* muscle isoform creatine kinase. To better distinguish the expression pattern between these two isoforms, we amplified by PCR a cDNA fragment corresponding to the muscle isoform and used it as a probe. The results indicate that they exhibit both overlapping and distinct expression. The brain isoform is uniformly expressed in the ectoderm during gastrulation and neurulation (not shown). Beginning from the tail-bud stage (stage 25), it can be weakly detected in the somites (Fig. 5A, B). As development proceeds, strong expression is detected in the somites (Fig. 5C, D). At larval stage, strong expression persists in the somites, other sites such as head muscle, the heart region and the pronephric duct also express the transcripts corresponding to the brain isoform (Fig. 5E).

The muscle isoform *creatine kinase* is restricted in the somites. It is not detectable during gastrulation (not shown). At neurula stage, it is expressed in the formed somites at the trunk region (Fig. 6A, B). Strong expression in the somites persists as development proceeds (Fig. 6C-F). At larval stage, it is also strongly expressed in the head muscle and in the hypaxial muscle cells migrating away from the somites, a diffuse expression could be observed in the heart region (Fig. 6G). Unlike the brain isoform, the muscle isoform is not expressed in the pronephros. Thus, this expression pattern is much similar or identical as other muscle

TABLE 1

cDNA CLONES IDENTIFIED BY WHOLE-MOUNT *IN SITU* HYBRIDIZATION SCREENING

cDNA clones	Genes	Accession numbers	Probe regions
21A04	<i>Purine nucleoside phosphorylase</i>	BC054317	3'-UTR
6D08	<i>Acetylcholine receptor α1a</i>	X07067, X17244	aa 102 onward
27F11	<i>Aspartate aminotransferase</i>	BC106292	aa 331 onward
4A07	<i>Glycine amidinotransferase</i>	AF187863, BC047973	aa 24 onward
6F01	<i>Creatine kinase, brain isoform</i>	BC042282	aa 268 onward
	<i>Creatine kinase, muscle isoform</i>	BC042249	aa 94 to 342

marker genes such as muscle actin and myosine light chain. These results suggest that the brain isoform creatine kinase is also strongly expressed in the somites while the muscle isoform exhibits indeed a restricted expression in the somites. Although the two isoforms have a higher overall identity at the protein level, the nucleotide sequences of the coding region are significantly divergent, and the 3' non-coding regions do not have any similarity. Thus, we can exclude the possibility of a cross-reactivity.

Materials and Methods

Whole-mount *in situ* hybridization screening of a gastrula cDNA library was previously described (Bourdela *et al.*, 2004). The muscle isoform *creatine kinase* was PCR amplified according to published sequence (accession number BC042249) using the following primers: upstream, (5'-ATTGAGGATCGTCACGGTGG-3'; downstream, 5'-GCGTCTGAAGACTTCTTTCAT-3'. The PCR product was cloned in the T-easy vector, linearized by *Nco* I and transcribed with SP6 RNA polymerase to obtain antisense probe.
